# A Dynamic Efficiency Model for Local Exchange Carriers

## Abstract

We analyze a dataset containing costs and outputs of 67 American local exchange carriers in a period of 11 years. This data has been used to examine the efficiency of British Telecom and KPN (Dutch telecom) using static stochastic frontier models. We show that these models are dynamically misspecified. As an alternative we provide an efficiency correction model. This model makes it possible to distinguish between unmeasured firm heterogeneity, firm inefficiency and measurement error, by assuming time invariant unmeasured firm heterogeneity and firm efficiency, which evolves over time.

*Keywords:* Error Correction; Panel Data; Random Effects; Stochastic Frontier.

## 1 Introduction

In this paper we introduce a stochastic frontier model for panel data that combines unobserved heterogeneity and firm specific stochastic dynamic efficiency changes. An essential aspect of the model is that it contains time independent random firm effects. We show empirically that specifying these effects as fixed disregards cross section evidence that is needed to provide a good specification of the frontier. Simple regressions on the means and deviations from the means separately illustrate this. They also make clear that static models are misspecified: the two sources of information give contradictory evidence. A dynamic version, similar to error correction models, appears to give a huge improvement in the likelihood. In this model the changes in efficiency depend on the distance from the frontier, which led to the name efficiency correction model (EFCOM). The model is suited to identify the efficiency of a firm over time as well as unobserved heterogeneity.

A survey of stochastic frontier models is given by Greene (2005). Farsi et al. (2006) show that the choice to include unobserved heterogeneity is crucial for the estimates of efficiency. Stochastic dynamics in efficiencies, not treated in Greene, are used in Ahn, Good and Sickles (2000) (henceforth AGS), but in their models they don't include unobserved heterogeneity in the efficiency frontier and use fixed firm effects. Wang and Ho (2010) use fixed effects for unobserved heterogeneity and dynamics somewhat different from AGS and ours.

We apply EFCOM on two sets of panel data to estimate cost efficiencies. Both datasets consist of cost and output variables per year for several firms and have previously been analyzed in the literature with a static model.

The main dataset relates to 67 U.S. local exchange carriers (LEC's) over the years 1996 to 2006. The data has been analyzed by NERA Economic Consulting (2005, 2006) to examine the cost efficiency of the British BT and the Dutch KPN respectively, using the static model.

To investigate whether our model also applies in another context we analyzed a second dataset. This dataset concerns 382 U.S. nonteaching hospitals over the years 1987 to 1991, and has previously been analyzed in Koop et al. (1997), using Bayesian tools for inference in the static model.

For both datasets we show that the models without firm specific efficiency dynamics are clearly misspecified and that the efficiency correction model provides a much better fit to the data. Moreover there is a striking similarity in outcomes for both datasets.

Following Griffin and Steel (2007) the main estimation results are obtained by the Bayesian package WinBUGS, using Markov Chain Monte Carlo (MCMC) techniques. However, we start our analysis with a classical explanation and estimation procedure of the main dynamic features. We show that maximum likelihood estimates and MCMC inference give very similar results in a simple dynamic model. In order to obtain estimates for all stochastic components in the efficiency correc-

tion model – the unobserved heterogeneities and efficiencies – MCMC methods are required. We obtain robust estimates of the efficiencies per year, insensitive to variations in model specification.

The setup of this article is as follows. In Section 2 we discuss the efficiency correction model in relation to the literature on stochastic frontier models. Section 3 provides a brief description of the LEC data. Section 4 provides a preliminary classical analysis and a comparison between maximum likelihood and MCMC outcomes for the LEC data from a simple dynamic stochastic frontier model. Sections 5 and 6 provide estimation results from the efficiency correction model for the local exchange carriers and hospitals, respectively. Section 7 concludes.

## 2 Model specifications

### 2.1 A general stochastic frontier model for panel data

We consider a general stochastic frontier model for panel data given by

$$y_{it} = \text{EF}_{it} + u_{it} + \varepsilon_{it}, \quad (1)$$

$$\text{EF}_{it} = \mu + x'_{it}\beta + \gamma_t + v_i, \quad (2)$$

where  $\text{EF}_{it}$  denotes the efficiency frontier. for  $i = 1, \dots, N$ ,  $t = 1, \dots, T$ , where  $N$  is the number of firms,  $T$  is the number of time periods, and  $x_{it}$  is a  $(k \times 1)$  vector of explanatory variables.  $u_{it}$ ,  $v_i$  and  $\varepsilon_{it}$  are respectively inefficiency, unobserved heterogeneity and measurement error, and efficiency is defined as  $\exp(-u_{it})$ . It is assumed that  $u_{it}$ ,  $v_i$ , and  $\varepsilon_{it}$  are distributed independently of each other, and  $\text{Cov}(\varepsilon_{it}, \varepsilon_{js}) = 0$  for  $s \neq t$ .  $\gamma_t$  is either a deterministic function of time or a stochastic process, being independent of  $u_{it}$ ,  $v_i$ , and  $\varepsilon_{it}$ . In our applications  $y_{it}$  denotes the logarithm of total cost and  $x_{it}$  is a vector of output components and environmental variables. The same model can be used for output or profit. In the latter case it is

assumed that  $u_{it} \leq 0$ .

It is important to understand how we identify the stochastic components within the model. Questions that need to be addressed are whether it makes sense to distinguish between unobserved heterogeneity and measurement errors, whether  $\gamma_t$  can be attributed to inefficiency, and whether the inefficiency term  $u_{it}$  can be distinguished from other terms.

Unobserved heterogeneity and measurement errors have the plausible structure  $v_i + \varepsilon_{it}$ . The fact that we call  $v_i$  unobserved heterogeneity is partly arbitrary; we could also include a part of  $\varepsilon_{it}$  in the unobserved heterogeneity. For the identification of inefficiency  $u_{it}$  – the goal of our analysis – this is of little importance. What is important is that we assume that  $\varepsilon_{it}$  has no autocorrelation structure.

The firm independent time term,  $\gamma_t$ , is well identified in our applications with many firms and short time periods in the form of time dummies. Whether these time effects must be attributed to general efficiency changes or other shifts in the cost function cannot be based on the available information. One may say that absolute inefficiency is only well identified in deviation of the yearly means.

This still leaves the problem of how to distinguish between  $v_i$  (or  $v_i + \varepsilon_{it}$ ) and  $u_{it}$ . There are two statistical sources of information to identify  $v_i$  and  $u_{it}$ . The first is that  $u_{it}$  is positive and skewed to the right, while the other terms are symmetrical. The second source is the autocorrelation structure of  $u_{it}$ .

We have chosen for a model where  $v_i$  is the symmetrically distributed unobserved heterogeneity, while  $u_{it}$  is a first order autoregressive process with positive innovations. We will argue that these assumptions are plausible. This model appears to be well identified.

We might as well include time invariant inefficiencies. However, this component is very hard to distinguish from  $v_i$  statistically. With noninformative priors it is even theoretically difficult to make this distinction, as is shown by Fernández et al. (1997). Strong informative priors will give a result, but the posteriors will hardly

differ from the priors.

Because it is impossible to specify a unique and complete model for cost components, we think that unobserved heterogeneity  $v_i$  should be included in the efficiency frontier. A detailed discussion on unmeasured heterogeneity in stochastic frontier models is provided by Greene (2005). Farsi et al. (2006) show in a static context the impact of the inclusion of unobserved heterogeneity  $v_i$  on the estimates of efficiency. They show that models including  $v_i$  underestimate efficiency and models without  $v_i$  overestimate efficiency, providing lower and upper bounds for companies' efficiency scores. In a specific example they show that the correlation between the efficiencies scores and ranks in both models is approximately zero.

In the remainder of this paper we shall concentrate on model (1)–(2). We do not consider the case where  $x_{it}$  is stochastic and  $\beta$  is allowed to vary over time and clusters. For these extensions, see Tsionas (2002) and Kumbhakar and Tsionas (2005), who distinguish between technical and allocative efficiency, allowing  $\beta$  to vary over clusters. In Tsionas and Kumbhakar (2004),  $\beta$  is allowed to vary over time and clusters in a Markov switching stochastic frontier model. We will investigate dynamics of the form  $u_{it} = u_i\omega_t$ , which assumes a common (deterministic) function for the evolution of inefficiency over time, see for instance Cornwell et al. (1990), Battese and Coelli (1992), and Griffin and Steel (2007). We use this deterministic model as a benchmark.

Examples of models in the literature, which include stochastic dynamics without unobserved heterogeneity in the efficiency frontier are: AGS, who use the generalized method of moments for estimation; Desli et al. (2003), who use maximum likelihood estimation; Tsionas (2006), using Gibbs sampling for inference, and Park et al. (2003, 2007), who use nonparametric estimation methods.

In this paper, we do include unobserved heterogeneity. Following Farsi et al. (2006) we assume that the unobserved heterogeneity is time independent, while inefficiency is time dependent.

## 2.2 Autocorrelation and efficiency correction

We assume that the inefficiency  $u_{it}$  follows a first order autoregressive process [AR(1)], given by

$$u_{it} = (1 - \delta_1)u_{i,t-1} + \eta_{it}, \quad (3)$$

where the  $\eta_{it}$ 's are identical and independently distributed. This is a plausible assumption, also made by AGS: firms adapt partly to inefficiencies. Note that this is not a standard AR(1) process as  $u_{it} > 0$ . The distributional assumptions of  $\eta_{it}$  will be specified later on.

By rewriting model (1)–(3) in an ‘error correction’ format it will be shown that it has some implausible consequence. This formulation is in terms of levels and first differences, where the first difference in  $y_{it}$  depends on the deviation between the cost and the efficiency frontier in the preceding period,  $y_{i,t-1} - \text{EF}_{i,t-1}$ , given by

$$y_{i1} = \text{EF}_{i1} + u_{i1} + \varepsilon_{i,1}, \quad (4)$$

$$\Delta y_{it} = -\delta_1(y_{i,t-1} - \text{EF}_{i,t-1}) + \Delta \text{EF}_{it} + \eta_{it} + \varepsilon_{it} - (1 - \delta_1)\varepsilon_{i,t-1}, \quad (5)$$

where  $\Delta$  is the first difference operator and  $\Delta z_t = z_t - z_{t-1}$ . For  $\delta_1 = 1$  Eqs. (4)–(5) are equivalent to Eqs. (1)–(2). The efficiency correction formulation shows the implication that firms adjust their cost level to the inefficiency in the preceding period for a fraction  $\delta_1$ , and *fully* to the change in the efficiency level,  $\Delta \text{EF}_{it}$ . For economical and technical reasons this seems to be impossible. Adjustment to  $\Delta \text{EF}_{it}$  will also be partial.

We introduce partial adjustment to  $\Delta \text{EF}_{it}$  by redefining Eq. (1), leading to

$$y_{it} = \text{EF}_{it} - (1 - \delta_2)\Delta \text{EF}_{it} + u_{it} + \varepsilon_{it}, \quad (6)$$

$$\text{EF}_{it} = \mu + x'_{it}\beta + \gamma_t + v_i, \quad (7)$$

$$u_{it} = (1 - \delta_1)u_{i,t-1} + \eta_{it}. \quad (8)$$

Note that the definition of inefficiency  $u_{it}$  has been changed to

$$u_{it} = y_{it} - (\delta_2 \text{EF}_{it} + (1 - \delta_2) \text{EF}_{i,t-1}) - \varepsilon_{it}, \quad (9)$$

so the actual attainable efficiency is based on weighted average of the efficiency frontier of the current and preceding period. When the model for the efficiency frontier contains stock variables (capacity) and  $y_{it}$  is a flow variable this structure is compelling (the stock changes through the period). More in general the impossibility to react immediately on changes gives a motivation. The model (6)–(8) can be expressed in ‘error correction’ format,

$$y_{i1} = \text{EF}_{i1} - (1 - \delta_2) \Delta \text{EF}_{it} + u_{i1} + \varepsilon_{i1}, \quad (10)$$

$$\begin{aligned} \Delta y_{it} &= -\delta_1 (y_{i,t-1} - \text{EF}_{i,t-1}) + \delta_2 \Delta \text{EF}_{it} + (1 - \delta_1)(1 - \delta_2) \Delta \text{EF}_{i,t-1} \\ &+ \eta_{it} + \varepsilon_{it} - (1 - \delta_1) \varepsilon_{i,t-1}. \end{aligned} \quad (11)$$

On the basis of this representation we call the model (6)–(8) the efficiency correction model (EFCOM).

Additional assumptions have to be made about the initial inefficiencies and the distributions of the innovations  $\eta_{it}$ . We assume covariance stationarity, implying that the unconditional moments are provided by

$$\text{E}(u_{it}) = \text{E}(\eta_{it})/\delta_1, \quad (12)$$

$$\text{Var}(u_{it}) = \text{Var}(\eta_{it})/(1 - (1 - \delta_1)^2). \quad (13)$$

In general the unconditional distribution is not the same as the distribution of the innovations. In the case that  $\eta_{it}$  has a gamma distribution, denoted by  $\eta_{it} \sim \text{G}(\phi, \lambda)$ , where  $\text{E}(\eta_{it}) = \phi/\lambda$  and  $\text{Var}(\eta_{it}) = \phi/\lambda^2$ , the unconditional distribution can be approximated by a gamma distribution,  $u_{it} \sim \text{G}(\lambda(2 - \delta_1), \phi(2 - \delta_1)/\delta_1)$ . This follows from the moment conditions (12)–(13) and can be demonstrated by simulation. In

our applications we assume that the innovations  $\eta_{it}$  have a gamma distribution.

An alternative to the AR(1) with gamma innovations as defined in (8), is provided by Tsionas (2006). He assumes that the log of inefficiency follows a first order autoregressive process, i.e.  $\ln u_{it} = z'_{it}\gamma + (1 - \delta)\ln u_{i,t-1} + \eta_{it}$ , where  $\eta_{it} \sim N(0, \sigma_\eta^2)$  and  $z_{it}$  is a vector of additional explanatory variables.

Another option for the AR(1)-process would be to use a conditional Gamma model for the inefficiency process, replacing Eq. (8) by  $u_{it}|u_{i,t-1} \sim G(\phi, \phi/m(u_{i,t-1}))$ , where  $m(u_{i,t-1}) = E(u_{it}|u_{i,t-1}) = (1 - \delta_1)u_{i,t-1} + \mu_i\delta_1$  and  $\mu_i$  is the unconditional expectation of  $u_{it}$ . The unconditional variance is provided by

$$\text{Var}(u_{it}) = \frac{\mu_i^2/\phi}{1 - (1 - \delta_1)^2(\phi + 1)/\phi}, \text{ for } 0 \leq 1 - \delta_1 < \left(\frac{\phi}{\phi + 1}\right)^{1/2} < 1,$$

see Grunwald et al. (2000) for more details.

The EFCOM model (6)–(8) has most resemblance with that of AGS. In both models it is assumed that inefficiencies follow a first order autoregressive process, however AGS do not specify the distribution of  $\eta_{it}$ . The main differences are:

- AGS do not adjust the efficiency frontier for the implausible implication of full immediate response in changes in the efficiency frontier.
- AGS do not include unobserved heterogeneity  $v_i$  in the efficiency frontier. They assume fixed effects (denoted by  $\lambda_i$ ), which they attribute completely to inefficiencies. Empirically, the difference is that between a random effects model with standard error  $\sigma_v$  and a fixed effects estimator. Our estimates of  $\sigma_v$  will appear to be reasonable and certainly finite. Very large estimates would mean that approximation by a fixed effects model is justified. As will be shown in Section 4 the random effects model is essential to retain the information on the regression coefficients ( $\beta$ ).

Whether differences on the firm level must be attributed to unobserved heterogeneity or inefficiencies is a matter that in our view cannot be decided on

statistical grounds alone. In our opinion at least part of the effects must be attributed to unobserved heterogeneity.

- There are some differences in the treatment of time effects  $\gamma_t$ . Both models have in common that they concern relative (no absolute) inefficiencies.
- We use MCMC methods for model inference, which allows us to estimate all unobserved components. AGS use the generalized method of moments which has very limited possibilities to do so.

### 3 Data

Stochastic frontier models have been used in practice to compare cost efficiency for fixed line telecommunication operators. Two recent examples of these benchmark studies are performed by NERA (2005, 2006) under the authority of Ofcom (Office of Communication) and OPTA (Independent Post and Telecommunications Authority) to examine the cost efficiency of the British BT and the Dutch KPN respectively. These studies are based on the costs and outputs of American local exchange carriers (LEC), for which data is freely available.

In this article we use yearly data from 67 LEC's over a period of 11 years from 1996 until 2006. The costs are the sum of operating costs, depreciation and cost of capital. Output is measured by the number of switched and leased lines, switch minutes, and the length of cable sheath. Environmental explanatory variables are the proportion of business to residential lines and the population density. All variables are measured in natural logs. The variables and their abbreviations are given in Table 1. Detailed information on the different variables can be found in the report by NERA (2006). Table 2 contains averages of the variables over the LEC's per year. The averages of cost, leased lines, sheath, business to residential ratio and population density increase over time, while the averages of switched lines and switch minutes decrease over time. There are large differences between LEC's with

respect to cost and output variables; the difference between minimum and maximum cost is a factor 15. Some values of switch minutes and depreciation cost are missing for some LEC's in the years 2005 and 2006. The missing values are replaced by estimates, based on an interpolation or extrapolation of the specific series. In our applications the leased lines, switch minutes and sheath are specified in deviation from switched lines, indicated by asterisks, meaning that the coefficient of switched lines refers to the economies of scale.

## 4 Preliminary model exploration

The purpose of this Section is threefold. First, we show that a simple informal ordinary least squares (OLS) test reveals that a random effects model (REM) without autocorrelation is misspecified. Next an error correction random effects model (ECREM) is introduced, reflecting the basic dynamic structure of the efficiency correction model (6)–(8). Finally it is shown that for (error correction) random effects models there is a close correspondence between the estimation results obtained by maximum likelihood and WinBUGS. The latter is the program for Bayesian inference that will be used for the efficiency correction model in the next Section.

The random effects model without autocorrelation is provided by

$$y_{it} = \mu + x'_{it}\beta + \gamma_t + \theta_i + \alpha_{it}, \theta_i \sim N(0, \sigma_\theta^2) \text{ and } \alpha_{it} \sim N(0, \sigma_\alpha^2), \quad (14)$$

where it is assumed that  $\theta$  and  $\alpha$  are uncorrelated. To prevent confusion we use the symbols  $\theta$  and  $\alpha$  to indicate that in this Section no distinction is made between inefficiency, unobserved heterogeneity and measurement error.

The data can be split in two independent parts, in means and deviation from

means,

$$\bar{y}_i = \mu^* + \bar{x}'_i \beta + \theta_i + \bar{\alpha}_i, \quad (15)$$

$$\tilde{y}_{it} = \tilde{x}'_{it} \beta + \tilde{\gamma}_t + \tilde{\alpha}_{it}, \quad (16)$$

where  $\bar{z}_i = T^{-1} \sum_{t=1}^T z_{it}$ , and  $\tilde{z}_{it} = z_{it} - \bar{z}_i$  for  $z = y, x, \gamma$ , and  $\alpha$ , and  $\mu^* = \mu + \bar{\gamma}$ . The two sources of information, means and deviations from the means, are independent and should reinforce each other. The assumption that  $\beta$  is the same in (15) and (16) can be informally checked by comparing the OLS estimates of  $\beta$  in both equations. The estimate of  $\beta$  in the random effects model (14) is a weighted average of the estimates of  $\beta$  in (15) and (16), with weights depending on  $\sigma_\theta^2$  and  $\sigma_\alpha^2$ .

Estimates of the variances  $\sigma_\alpha^2$  and  $\sigma_\theta^2$  may be obtained from regression on the means (15) and deviations (16) from the means:  $\hat{\sigma}_\alpha^2 = RSS_D / (N(T-1) - k)$ , and  $\hat{\sigma}_\theta^2 = RSS_M / (N - k) - \hat{\sigma}_\alpha^2 / T$ , where  $RSS_M$  and  $RSS_D$  are the residual sum of squares from (15) and (16), respectively.

The first three panels in Table 4 present estimation results for the REM (14) and the model in means (15), and deviations (16) for the LEC data. The models in means and deviations from the means are estimated by OLS. The REM parameter  $q_\theta = \sigma_\theta^2 / \sigma_\alpha^2$  is estimated by maximizing the concentrated loglikelihood with respect to  $\mu$ ,  $\beta$ ,  $\gamma$ , and  $\sigma_\alpha$ , see the column REM (ML) in Table 4.

The estimation results for  $\beta$  are very different from each other. We focus on the most important variable  $\ln(\text{SL})$ , reflecting the economies of scale. The economies of scale parameter in the means model is, as expected, 0.98, approximately one, with a low standard error (0.019), while in the deviations model this parameter is only 0.59, with a larger standard error (0.048). The information from the means is dominant. This is due to the fact that the explanatory variable, the scale, has a large variance over companies. Fixed effects models disregards this important

cross-sectional information on  $\beta$ . In the REM the estimate of the economies of scale parameter is almost 1, illustrating the dominance of the information from the means.

When  $\sigma_\theta$  and  $\sigma_\alpha$  are estimated from the model in means (15) and deviations (16) separately, one obtains  $\hat{\sigma}_\alpha = 0.057$  and  $\hat{\sigma}_\theta = 0.120$ . The estimate  $\hat{\sigma}_\theta$  contrasts to the maximum likelihood estimate from REM, being 0.271, another indication that REM is misspecified.

The fourth panel of Table 4 presents the Bayesian estimation results for the random effects model (14). Noninformative normal distributed priors are assumed for the place parameters  $\mu$ ,  $\beta$ , and  $\gamma_t$  and noninformative gamma distributed priors for  $\sigma_\theta^{-2}$  and  $\sigma_\alpha^{-2}$ . The Bayesian estimation results are almost the same as the results from maximum likelihood. Table 4 also provides the model selection criterion DIC, see Spiegelhalter et al. (2002). DIC is minus two times the loglikelihood in the posterior means plus two times a penalty for model complexity, measuring the “effective number of parameters” and denoted by  $p_D$ .

It is clear from Table 4 that the random effects model (14) is misspecified. As mentioned in Subsection 2.2 this might be the result of the unrealistic assumption in the random effects model that firms fully adjust their cost to output.

This assumption is relaxed in the error correction random effects model (ECREM), defined as

$$y_{i1} = \mu + x'_{i1}\beta + \gamma_1 + \theta_i + \alpha_{i1}, \quad (17)$$

$$\Delta y_{it} = -\delta_1(y_{i,t-1} - \mu - x'_{i,t-1}\beta - \gamma_{t-1} - \theta_i) + \delta_2\Delta(x'_{it}\beta + \gamma_t) + \eta_{it}, \quad (18)$$

where  $\theta_i \sim N(0, \sigma_\theta^2)$ ,  $\eta_{it} \sim N(0, \sigma_\eta^2)$  and  $\theta$  and  $\eta$  are uncorrelated. Further we assume covariance stationarity for  $\alpha_{it}$ , so

$$\alpha_{i1} \sim N(0, \sigma_\eta^2 / (1 - (1 - \delta_1)^2)). \quad (19)$$

For  $\delta_1 = \delta_2 = 1$  the error correction random effects model (17)–(19) coincides with

the random effects model (14).

The first three panels of Table 5 contain the estimation results from ECREM for three different cases, namely  $\delta_2 = 1$ ,  $\delta_1 = \delta_2$ , and the general case  $0 < \delta_1, \delta_2 < 1$ . The parameters  $q_\theta = \sigma_\theta^2/\sigma_\eta^2$ ,  $\delta_1$  and  $\delta_2$  are estimated by maximizing the concentrated loglikelihood with respect to  $\mu$ ,  $\beta$ ,  $\gamma$  and  $\sigma_\eta$ . By introducing only 2 variables the loglikelihood increases by more than 228 points compared to the random effects model (14). The difference in loglikelihood between the most and least restrictive model is more than 30 points at the cost of only 1 parameter. The estimates of  $\delta_1$  in all three cases are far from 1, the value that is assumed in the random effects model. It can be concluded that the REM is dynamically misspecified. The fourth panel of Table 5 contains the Bayesian estimation results for the case  $\delta_2 = 1$ . Similar to the random effects model noninformative priors for place and scale parameters are assumed. For  $\delta_1$  a uniform prior between 0 and 1 is assumed. The results almost coincide with the estimation results by maximum likelihood in the first panel. The DIC decreases by 151 points compared to the random effects model, being consistent with the increase in loglikelihood.

## 5 Efficiency correction model

In this Section the estimation results from the efficiency correction model (6)–(8) are presented. Compared to the error correction random effects model in the previous Section, the essential new element is the inclusion of measurement errors and the interpretation of the different error components.

We choose to omit the first year in the evaluation of the likelihood because  $x_{i0}$  in  $\Delta x_{i1}$  is unknown. An alternative would have been to include the first year and replace  $\Delta x'_{i,1}\beta$  by a stochastic variable, with moments determined by those of  $\Delta x'_{i,t}\beta$  in later years, so assuming a model for  $\Delta x'_{i,t}$ . This approach complicates the estimation procedure and has little effect on the results as the first observation gets

little weight in the evaluation.

We make the following distributional assumptions for the efficiency correction model, given by Eq. (6)–(8). The measurement errors  $\varepsilon_{it}$  have a student  $t$ -distribution to account for possible outliers. The unobserved heterogeneity  $v_i$  have a normal distribution, while the initial inefficiencies  $u_{i2}$  and the innovations  $\eta_{it}$  have a gamma distribution. For  $\gamma_t$  we simply use dummy variables. This can be summarized by

$$\begin{aligned} \varepsilon_{it} &\sim t_\nu(0, \sigma_\varepsilon^2), & v_i &\sim N(0, \sigma_v^2), \\ u_{i2} &\sim \text{Gamma}(\phi_1, \lambda_1), & \eta_{it} &\sim \text{Gamma}(\phi, \lambda). \end{aligned}$$

From the covariance stationarity assumptions (12)–(13) it follows that

$$\phi = \frac{\delta_1}{2 - \delta_1} \phi_1, \text{ and } \lambda = \frac{1}{2 - \delta_1} \lambda_1.$$

The parameters to be estimated are  $\mu, \beta, \kappa, \delta_1, \delta_2, \phi_1, \lambda_1, \sigma_v, \sigma_\zeta, \sigma_\varepsilon$ , and  $\nu$ . Before specifying priors for these parameters it is useful to examine how well the parameters are identified. Because the place parameters are well identified, we compute the first and the second moments for the efficiency correction model without  $\beta, \delta_2$  and  $\gamma_t$ , given by

$$y_{it} = \mu + v_i + u_{it} + \varepsilon_{it}, \quad u_{it} = (1 - \delta_1)u_{i,t-1} + \eta_{it},$$

which may be rewritten as

$$y_{i2} = \mu + v_i + u_{i2} + \varepsilon_{i2}, \quad \Delta y_{it} = -\delta_1 u_{i,t-1} + \eta_{it} + \varepsilon_{it} - \varepsilon_{i,t-1}.$$

This model contains 7 parameters:  $\mu, \delta_1, \phi_1, \lambda_1, \sigma_v, \sigma_\varepsilon$ , and  $\nu$ . The first and second moments of  $y_{i2}$  are provided by

$$E(y_{i2}) = \mu + \phi_1/\lambda_1, \quad \text{Var}(y_{i2}) = \sigma_v^2 + \phi_1/\lambda_1^2 + \nu/(\nu - 2)\sigma_\varepsilon^2.$$

The other relevant moments follow from the ARMA(1,1) structure of  $\Delta y_{it}$ , and are

given by

$$\begin{aligned}\text{Var}(\Delta y_{it}) &= 2(\delta_1 \phi_1 / \lambda_1^2 + \nu / (\nu - 2) \sigma_\varepsilon^2), \\ \text{Cov}(\Delta y_{it}, \Delta y_{i,t-1}) &= -\delta_1^3 \phi_1 / \lambda_1^2 - \nu / (\nu - 2) \sigma_\varepsilon^2, \\ \text{Cov}(\Delta y_{it}, \Delta y_{i,t-2}) &= -\delta_1^3 (1 - \delta_1) \phi_1 / \lambda_1^2.\end{aligned}$$

Note that  $E(\Delta y_{it}) = 0$  due to the stationarity requirement.

Identification of the degrees of freedom  $\nu$  follows from the fourth moments. In case of outliers,  $\nu$  will be low. Given  $\nu$  the parameters  $\phi_1 / \lambda_1^2$ ,  $\delta_1$ ,  $\sigma_\varepsilon^2$  and  $\sigma_v$  can be identified from the variances and covariances equations. The first and second moments are not sufficient to distinguish between  $\mu$  and the mean of the inefficiency  $\phi_1 / \lambda_1$ . Only the sum is given as the expectation of  $y_{i2}$ . The essential additional information must come from the third moment of  $u_{i2}$ , which has skewness  $2/\sqrt{\phi_1}$ .

For the remaining parameters practically noninformative priors are specified:

$$\begin{aligned}\sigma_\varepsilon^{-2} &\sim \text{Gamma}(0.1, 0.1), & \nu &\sim \text{Exp}(1/3), \\ \delta_1 &\sim \text{Uniform}(0.5, 0.95), & \delta_2 &\sim \text{Uniform}(0.5, 0.95), \\ \sigma_v^{-2} &\sim \text{Gamma}(0.1, 0.1), & \mu &\sim N(0, 100), \\ \phi_1^{-1} &\sim \text{Gamma}(3, 4), & \beta &\sim N(0, 100I), \\ \lambda_1 &\sim \text{Gamma}(\phi_1, -\ln(0.875)).\end{aligned}$$

The prior for  $\phi_1$  and  $\lambda_1$  is equal to the one used by Griffin and Steel (2007).

The efficiency correction model is estimated by WinBUGS. The inclusion of the measurement errors  $\varepsilon_{it}$  offers the possibility to generate the unobserved heterogeneity  $v_i$  and the efficiencies  $u_{it}$  as “parameters” in the MCMC process. This enables us to use the distribution of the measurement errors  $\varepsilon_{it}$  for the computation of the likelihood. Other setups are possible but more complex, because the efficiencies have to be positive.

Table 6 contains estimation results from a benchmark model and the efficiency correction model for 67 local exchange carriers from 1997 until 2006. In the benchmark model the inefficiency follows a deterministic function over time. Moreover, firms fully adjust their cost level to the change in the efficiency level. The benchmark model is provided by

$$y_{it} = \text{EF}_{it} + u_{it} + \varepsilon_{it}, \quad (20)$$

$$\text{EF}_{it} = \mu + x'_{it}\beta + \gamma_t + v_i, \quad (21)$$

$$u_{it} = u_{i1} \times \exp((t-2)\kappa), \quad (22)$$

where the prior for  $\kappa$  is given by  $\kappa \sim N(0, 1)$ . Table 6 contains a restricted version ( $v_i = 0$ ) of the benchmark model (Benchmark 1) and an unrestricted one (Benchmark 2). For the efficiency correction model 3 versions are provided:  $\delta = 1$  (ECM 1),  $v_i = 0$  (ECM 2), and an unrestricted one (ECM 3).

We will first discuss the results for the unrestricted efficiency correction model (ECM 3). The measurement errors are low ( $\sigma_\varepsilon = 0.040$ ), and the degrees of freedom  $\nu$  are approximately 17. Inspection of the data shows that rather dramatic changes took place during the sample period. Mergers and takeovers took place after the liberalization of the market for LEC's in 1996 and huge technological shifts occurred.

The estimates of  $\beta$  reveal that only a simple model remains: economies of scale are hardly above 1, and only two additional significant coefficients. The unobserved heterogeneity has a standard deviation  $\sigma_v = 0.175$ . Given the huge technological shifts and differences in circumstances in the various states of the USA this standard deviation seems reasonable.

The estimate of  $\gamma_t$  shows a decrease in cost level during the first two years followed by a steady increase. Evidently, many changes occurred in the sample period, which can be seen from large and irregular yearly changes.

The estimates of  $\delta_1 = 1 - \rho$  and  $\delta_2$  are clearly different from 1 and have small

standard deviations. It is difficult to explain intuitively why  $\delta_2$  is so much larger than  $\delta_1$ .

The covariance stationarity restrictions make sure that the results for  $(\phi, \lambda)$  follow directly from those for  $(\phi_1, \lambda_1)$ . The expectation of  $u_{i2}$ ,  $\phi_1/\lambda_1$ , is very well identified: 0.214 with a standard deviation of 0.041. The standard deviation,  $\sqrt{\phi_1}/\lambda_1$  is also well identified: 0.071 with a standard deviation of 0.008.

The DIC criterion cannot be compared directly to that of the error correction random effects model (17)–(19) in Table 4, because the latter results are based on the whole sample. Estimation of ECREM on the dataset without the first year gives a DIC of -1911.2. The efficiency correction model leads to a gain in DIC of 268 points.

Table 7 gives the posterior means of the inefficiency levels  $u_{it}$  and the unobserved heterogeneity  $v_i$  for all local exchange carriers. The autocorrelations of the  $u_{it}$  are as expected: the correlation between  $u_{i2}$  and  $u_{it}$  is around  $(1 - \delta_1)^{t-2}$ . Further the means of the inefficiencies over time  $\bar{u}_i$  and the unobserved heterogeneity  $v_i$  are almost uncorrelated (0.173). Note that the average inefficiency is almost constant over time.

If we compare in Table 6 the estimation results for the unrestricted efficiency correction model we can conclude the following:

1. Within the efficiency correction model the difference between assuming  $\delta = 1$  versus estimating  $\delta$  is not large in terms of DIC, only 2 points. Moreover, the correlation in the average efficiency  $\bar{u}_i$  between the 2 models is 0.995, see Table 8.
2. The difference between assuming  $v_i = 0$  and allowing for unobserved heterogeneity is large in terms of DIC, almost 100 points. However, the correlation in the average efficiency  $\bar{u}_i$  between the 2 models is 0.898, see Table 8.
3. The difference in DIC between the benchmark and the efficiency correction

models is substantial (inefficiency over time: deterministic function versus first order autoregressive model), more than 150 points. Moreover, the correlation in the average efficiencies  $\bar{u}_i$  between the benchmark and efficiency correction model are quite low, apart from the correlation between Benchmark 1 and ECM 2.

4. If the efficiency should be measured as  $u_{it} + v_i$  the efficiency results change enormously. The correlation between  $\bar{u}_i + v_i$  and  $\bar{u}_i$  is quite low: for Benchmark 2: 0.181, for ECM 1: 0.382 and for ECM 3: 0.375.

## 6 Application to hospital data

NEEDS TO BE UPDATED

In this Section the same analysis as done for the LEC's is applied to the dataset of 382 hospitals over a time period of 5 years as analyzed in Koop et al. (1997), Griffin and Steel (2004, 2007) and Atkinson and Dorfman (2005). These studies do not use firm specific stochastic dynamic efficiency changes. The specification in Griffin and Steel (2004) assumes time invariant inefficiency  $u_i$ , unobserved heterogeneity is not included, while measurement errors are. A vague prior is used for the distribution of  $u_i$ , a Bayesian nonparametric method is used for estimation of  $u_i$ . Atkinson and Dorfman (2005) use a model with a deterministic specification for firm specific time varying inefficiency. For estimation they apply the Bayesian method of moments in a Gibbs sampling framework.

We only show the results from a simplified model without interaction effects<sup>1</sup>. The variables are provided in Table 3. The variable  $D$  is a scaling variable, so it's coefficient is the economy of scale parameter.

Table 9 provides the estimation results from the preliminary analysis as in Sec-

---

<sup>1</sup>Of course the interaction effects can be added to the efficiency correction model, but they are not important for our conclusion with respect to the misspecification of the static stochastic frontier model.

tion 4. The results are comparable to those for the LEC's: the economy of scale parameter  $D$  is 0.99 for the model in means (15), and 0.74 for the model in deviations (16). The results from REM (14) are thus based on a hypothesis that should be refuted.

Table 10 contains the estimation results from the error correction random effects models (17)–(19). They clearly perform better than the standard random effects model in Table 9. The loglikelihood gain due to the introduction of  $\delta_1$  and  $\delta_2$  is 235 points. In the model without restrictions (the third panel of Table 9) both  $\delta_1$  and  $\delta_2$  significantly differ from 1: the estimates of  $\delta_1$  and  $\delta_2$  are respectively 0.30 and 0.59, both with standard deviations that are relatively small.

The Bayesian estimation results from the error correction random effects models by WinBUGS are almost a copy of the maximum likelihood results. For the case  $\delta_2 = 1$  the DIC outcome is -4381 and the effective number of parameters  $p_D$  equals 267. This result can be compared to the “best” model in Griffin and Steel (2007), who also use WinBUGS for inference on the efficiency of hospitals. In a model with deterministic time varying inefficiency and no unobserved heterogeneity they obtain a DIC of 4834 with an effective number of parameters of 398. They use 28 additional explanatory variables (cross products) which clearly improves the fit. For convenience we stick to our simple model. When the observations from the first year are excluded in ECREM with  $\delta_2 = 1$ , the DIC and effective number of parameters  $p_D$  equal -3200 and 141, respectively. These results can be used to compare the outcomes from the efficiency correction model.

Note that the high values of  $p_D$  are due to the random effects. The penalty is a fraction of the number of firms  $N$ , where the fraction depends on  $\sigma_v$ . In case  $\sigma_v$  is large, the random effects model approaches a fixed effects model, resulting in a penalty  $N$ .

Table 11 provides the estimation results from the efficiency correction model (6)–(8). As the number of time periods is only 4, the time dependence is simply

modeled by dummy variables instead of a random walk with drift. The estimates of the time dummy variables reflect a steady cost increase.

The crucial parameters  $\delta_1$  (0.358) and  $\delta_2$  (0.617) have very low standard deviations and are clearly different from 1 and from each other. They are quite close to the estimates from the error correction random effects model. The DIC gain is more than 2500 points. However the  $p_D$  is extremely large, 1376, corresponding to 95% of the number of observations.

The economies of scale parameter  $D$  is, as expected, approximately 1. All regression coefficients are very significant. The estimate of  $\sigma_\varepsilon$  is only 0.014, but the very low value of the degrees of freedom for the student  $t$ -distribution,  $\nu = 2.2$ , suggests that there are some severe outliers. The estimate of  $\sigma_v$  (0.11) is very acceptable, and could even be lower when more explanatory variables were used.

The inefficiencies have an expectation of 0.135 and a standard deviation of 0.059. Both values are slightly lower than in the LEC's example. The similarity is of course mainly the result of the imposed restriction.

## 7 Conclusions

In this paper we introduced the efficiency correction model and estimated it using MCMC methods. The model performs well for local exchange carriers as well as hospitals. It is a clear improvement over existing models in terms of plausibility as well as statistical fit. The similarity of the outcomes for two sectors that are so different from one another, suggests general applicability.

The model provides rich information to judge the inefficiency of companies. Some aspects that might be improved, are the basic model – a loglinear model might be too simple – and the explanation of the mean efficiency shifts between the years. This holds in specific in a turbulent changing market as that for the local exchange carriers. The assumption we made that unobserved heterogeneity is time invariant and

that there are no time invariant inefficiencies might be questioned, but that raises difficult identification issues. Additional information is needed to decide whether a part of what we classified as unobserved heterogeneity should be attributed to fixed inefficiencies.

Benchmark model:  $y_{it} = \text{EF}_{it} + u_{it} + \varepsilon_{it}$ ,  $\text{EF}_{it} = \mu + x'_{it}\beta + \gamma_t + v_i$ ,  $u_{it} = u_{i2} \times \exp((t-2)\kappa)$ .

Benchmark 1:  $v_i = 0$ , Benchmark 2: unrestricted.

Efficiency correction model:  $y_{it} = \text{EF}_{it} - (1-\delta)\Delta\text{EF}_{it} + u_{it}$ ,  $\text{EF}_{it} = \mu + x'_{it}\beta + \gamma_t + v_i$ ,  $u_{it} = \rho u_{i,t-1} + \eta_{it}$ .

ECM 1:  $\delta = 1$ , ECM 2:  $v_i = 0$  and ECM 3: unrestricted.

Table 7: Inefficiencies of the LEC's per year in the efficiency correction model (6)–(8).

| LEC             | $u_{i,97}$ | $u_{i,98}$ | $u_{i,99}$ | $u_{i,00}$ | $u_{i,01}$ | $u_{i,02}$ | $u_{i,03}$ | $u_{i,04}$ | $u_{i,05}$ | $u_{i,06}$ | $\bar{u}_{i,\cdot}$ | $v_i$   |
